Abstract In recent years it has become evident that functional RNAs in living organisms are not just curious remnants from a primoridal RNA world but an ubiquitous phenomenon complementing protein enzyme based activity. Functional RNAs, just like proteins, depend in many cases upon their well-defined and evolutionarily conserved three-dimensional structure. In contrast to protein folds, however, RNA molecules have a biophysically important coarse-grained representation: their secondary structure. At this level of resolution at least, RNA structures can be efficiently predicted given only the sequence information. As a consequence, computational studies of RNA routinely incorporate structural information explicitly. RNA secondary structure prediction has proven useful in diverse fields ranging from theoretical models of sequence evolution and biopolymer folding, to genome analysis and even the design biotechnologically or pharmaceutically useful molecules.

Keywords: Functional RNA, Non-Coding RNA, RNA Secondary Structure Prediction, Conserved RNA Structures

1. Introduction

It is not hard to argue that **RNomics**, i.e., the understanding of functional RNAs (both ncRNA genes and functional motifs in protein-coding RNAs) and their interactions at a genomic level, is of utmost practical and theoretical importance in modern life sciences: The comprehensive understanding of the biology of a cell obviously requires the knowledge of the identity of *all* encoded

RNAs, the molecules with which they interact, and the molecular structures of these complexes (Doudna, 2000).

Structural genomics, the systematic determination of all macro-molecular structures represented in a genome, until very recently has been focused almost exclusively on proteins. Although it is commonplace to speak of *"genes and their encoded protein products"*, thousands of human genes produce transcripts that exert their function without ever producing proteins. The list of functional non-coding RNAs (ncRNAs) includes key players in the biochemistry of the cell. Many of them have characteristic secondary structures that are highly conserved in evolution. Databases (referenced below) collect the most important classes:

tRNA. Transfer RNAs are the adapters that translate the triplet nucleic acid code of RNA into the amino acid sequence of proteins. (Sprinzl et al., 1998)

rRNA. Ribosomal RNAs are central to the translational machinery. Recent results strongly indicate that peptide bond formation is catalyzed by rRNA. (Gutell et al., 2000; Szymanski et al., 2000; Van de Peer et al., 2000; Maidak et al., 2001; Wuyts et al., 2001)

snoRNA. Small nucleolar RNAs are required for rRNA processing and base modification in the eukaryotic nucleolus. (Samarsky and Fournier, 1999; Omer et al., 2000)

snRNA. Small nuclear RNAs are critical components of spliceosomes, the large ribonucleoprotein complexes that splice introns out of pre-mRNAs in the nucleus. (Zwieb, 1996)

tmRNA. The bacterial tmRNA (also known as 10Sa RNA or SsrA) was named for its dual tRNA-like and mRNA-like nature. tmRNA engages in a translation process, adding in trans a C-terminal peptide tag to the unfinished protein at a stalled ribosome. The tmRNA-directed tag targets the unfinished protein for proteolysis. (Zwieb and Wower, 2000; Williams, 2002)

RNase P. Ribonuclease P is responsible for the 5'-maturation of tRNA precursors. Ribonuclease P is a ribonucleoprotein, and in bacteria (and some Archaea) the RNA subunit alone is catalytically active in vitro, i.e. it is a ribozyme. (Brown, 1999). RNase MRP, which shares structural similarities with RNase P RNA, cleaves at a specific site in the precursor-rRNA transcript to initiate processing of the 5S rRNA

telRNA. Telomerase RNA. Telomeres are the specialized DNA protein structures at the ends of eukaryotic chromosomes. Telomerase is a ribonucleoprotein reverse transcriptase that synthesizes telomeric DNA. (Blackburn, 1999)

SRPRNA. The signal recognition particle is a universally conserved ribonucleoprotein. It is involved in the co-translational targeting of proteins to membranes. (Gorodkin et al., 2001)

miRNA. Micro-RNAs (Lagos-Quintana et al., 2001; Lau et al., 2001; Lee and Ambros, 2001) regulate gene expression by regulating mRNA expression by

a mechanism closely linked to RNA interference by small double stranded RNAs, see e.g. (Bosher and Labouesse, 2000; Matzke et al., 2001). They are cleaved from their precursors, the small temporal RNAs (**stRNAs**), by the enzyme *Dicer*.

In addition, there is a diverse list of ncRNAs with sometimes enigmatic function. We give just a few examples, see also the `Rfam` database (Griffiths-Jones et al., 2003): The 17kb *Xist* RNA of humans and the smaller roX RNAs of *Drosophila* play a key role in dosage compensation and X chromosome inactivation (Avner and Heard, 2001; Franke and Baker, 2000). Several large ncRNAs are expressed from imprinted regions. Many of these are cis-antisense RNAs that overlap coding genes on the other genomic strand, see e.g. (Erdmann et al., 2001). An RNA (meiRNA) regulates the onset of meiosis in fission yeast (Ohno and Mattaj, 1999). Human vaults are intracellular ribonucleoprotein particles believed to be involved in multidrug resistance. The complex contains several small untranslated RNA molecules (van Zon et al., 2001). No precise function is known at present for the human H19 transcript, the hrsω transcript induced by heat shock in *Drosophila*, or the *E.coli* 6S RNA, see e.g. (Erdmann et al., 1999).

Even though the sequence of the human DNA is known by now, the contents of about half of it remains unknown. The diversity of sequences, sizes, structures, and functions of the known ncRNAs strongly suggests that we have seen only a small fraction of the functional RNAs. Most of the ncRNAs are small, they do not have translated ORFs, and they are not polyadenylated. Unlike protein coding genes, ncRNA gene sequences do not seem to exhibit a strong common statistical signal, hence a reliable general purpose computational genefinder for noncoding RNA genes has been elusive. It is quite likely therefore that a large class of genes has gone relatively undetected so far because they do not make proteins (Eddy, 2001).

Another level of RNA function is presented by functional motifs within protein-coding RNAs. A few of the best-understood examples of structurally conserved RNA motifs in viral RNAs

○ An *IRES* (internal ribosomal entry site) region is used instead of a CAP to initialize translation by Picornaviridae, some Flaviviridae including Heptatitis C virus, and a small number of mRNAs, see e.g. (Rueckert, 1996; Huez et al., 1998; Pesole et al., 2001).

○ The TAR hairpin structure in HIV and related Retroviruses is the target for viral transactivation.

○ The RRE structure of Retroviruses serves as binding site for the Rev protein and is essential for the viral replication. The RRE is a characteristic five-fingered structural motif, see e.g. (Dayton et al., 1992).

○ The CRE hairpin (Witwer et al., 2001) in Picornaviridae is vital for replication.

Genes in eukaryotes are often interrupted by intervening sequences, *introns*, that must be removed during gene expression. Similarly, rRNAs are produced from a pre-rRNA that contains so-called internal and external transcribed spacers. These contain regions with characteristic secondary structures (Denduangboripant and Cronk, 2001). RNA splicing is the process by which these parts are precisely removed from the pre-mRNA and the flanking, functional exons are joined together (Green, 1991). Regulated mechanisms of alternative splicing allow multiple different proteins to be translated from a single RNA transcript. Mutations can affect splicing of certain introns, leading to abnormal conditions. For example a form of thalassemia, a blood disorder, is due to a mutation causing splicing failure of an intron in a globin transcript, which then becomes untranslatable, see e.g. (Stoss et al., 2000). The splicing of most nuclear genes is performed by the spliceosome; however, in many cases the splicing reaction is self-contained; that is, the intron — with the help of associated proteins — splices itself out of the precursor RNA, see e.g. (Mattick, 1994) for a review.

A textbook example of a functional RNA secondary structure is the *Rho*-independent termination in *E.coli*. The newly synthesized mRNA forms a hairpin in the 3'NTR that interacts with the RNA polymerase causing a change in conformation and the subsequent dissociation of the Enzyme-DNA-RNA complex. For a computational analysis of the *Rho*-independent transcription terminators we refer to (d'Aubenton Carafa et al., 1990).

Only part of the mature RNA is translated into a protein. At the beginning of the mRNA, just behind the cap, is a non-coding sequence, the so-called leader sequence (10-200nt) that may be followed by another non-coding sequence of up to 600nt. An increasing number of functional features in the untranslated regions of of eukaryotic mRNA have been reported in recent years (Pesole et al., 2001; Jacobs et al., 2002).

An extreme example are the Early Noduline genes. Enod40, which is expressed in the nodule primordium developing in the root cortex of leguminous plants after infection by symbiotic bacteria (Sousa et al., 2001), codes for an RNA of about 700nt that gives rise to two short peptides, 13 and 27 amino acids, respectively. The RNA structure itself exhibits significant conservation of secondary structure motifs (Hofacker et al., 2002), and might take part in localization of mRNA translation (Oleynikov and Singer, 1998), as in the case of the bicoid gene *bcd* of *Drosophila* (Macdonald, 1990).

2. RNA Secondary Structures and Their Prediction

As with all biomolecules, the function of RNAs is intimately connected to their structure. It does not come as a surprise therefore, that most the the classes of functional RNAs listed in the introduction have, like the well-known *clover-*

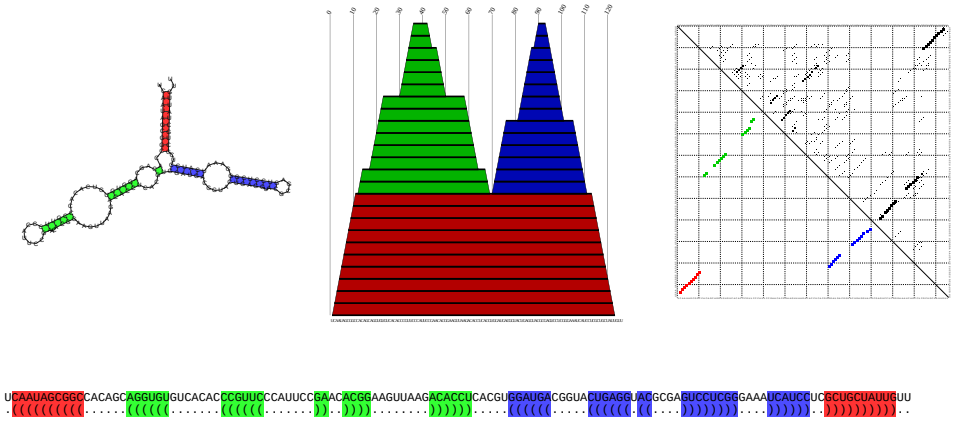

Figure 1.1. RNA secondary structure of an 5S ribosomal RNA. Secondary structure graph (left), mountain representations (middle), dot plot (right), and bracket notation (bottom).

leaf structure of tRNAs, distinctive structural characteristics. While successful predictions of RNA tertiary structure remain exceptional feats, RNA secondary structures can be predicted with reasonable accuracy, and have proven to be a biologically useful description.

A secondary structure of a given RNA sequence is the list of (Watson-Crick and wobble) base pairs satisfying two constraints: (i) each nucleotide takes part in at most one base pair, and (ii) base pairs do not cross, i.e., there are no knots or pseudo-knots. While pseudo-knots are important in many natural RNAs (Westhof and Jaeger, 1992), they can be considered part of the tertiary structure for our purposes. Secondary structure can be represented in various equivalent ways, see Fig. 1.1.

The restriction to knot-free structures is necessary for efficient computation by means dynamic programming algorithms (Nussinov et al., 1978; Waterman, 1978; Zuker and Stiegler, 1981; Zuker and Sankoff, 1984; Zuker, 1989; McCaskill, 1990; Schmitz and Steger, 1992; Hofacker et al., 1994; Wuchty et al., 1999; Hofacker et al., 2002). The memory and CPU requirements of these algorithms scale with sequence length n as $\mathcal{O}(n^2)$ and $\mathcal{O}(n^3)$, respectively, making structure prediction feasible even for large RNAs of about 10000 nucleotides, such as the genomes of RNA viruses (Hofacker et al., 1996; Huynen et al., 1996a; Witwer et al., 2001). There are two implementations of various variants of these dynamic programming algorithms: the `mfold` package by Michal Zuker, and the the `Vienna RNA Package` by the present authors and their collaborations. The latter is freely available from `http://www.tbi.univie.ac.at/`.

These thermodynamic folding algorithms are based on an energy model that considers additive contributions from stacked base pairs and various types of loops, see e.g. (Walter et al., 1994; Mathews et al., 1999). Two widely used methods for determining nucleic acid thermodynamics are absorbance melting curves and microcalorimetry, see (SantaLucia Jr. and Turner, 1997) for a review.

Recently, algorithms have been described that are able to deal with certain classes of pseudo-knotted structures, however at considerable computational cost (Rivas and Eddy, 1999; Akutsu, 2001; Lyngsø and Pedersen, 2000; Giegerich and Reeder, 2003). Alternatively, heuristics such as genetic algorithms can be used (Lee and Han, 2002). A common problem of all these approaches is the still very limited information about the energetics of pseudo-knots (Gultyaev et al., 1999; Isambert and Siggia, 2000).

3. Neutral Networks in Sequence Space

A more detailed analysis of functional classes of RNAs shows that their structures are very well conserved while at the same time there may be little similarity at the sequence level, indicating that the structure has actual importance for the function of the molecule. In order to understand the evolution of functional RNAs one therefore has to understand the relation between sequence (genotype) and structure (phenotype). Although qualitatively there is ample evidence for neutrality in natural evolution as well as in experiments under controlled conditions in the lab, very little is known about regularities in general genotype-phenotype relations. In the RNA case, however, the phenotype can be approximated by the minimum free energy structure of RNA, see e.g. (Schuster, 2001) for a recent review. This simplifying assumption is met indeed by RNA evolution experiments *in vitro* (Biebricher and Gardiner, 1997) as well as by the design of RNA molecules through artificial selection (Wilson and Szostak, 1999).

There is ample evidence for redundancy in genotype-phenotype maps f in the sense that many genotypes cannot be distinguished by an evolutionarily relevant coarse grained notion of phenotypes which, in turn, give rise to fitness values that cannot be faithfully separated through selection. Regarding the folding algorithms as a map f that assigns a structure $s = f(x)$ to each sequence x we can phrase our question more precisely: We need to know how the set of sequences $f^{-1}(s)$ that folds into a given structure s is embedded in the sequence space (where the genotypes are interpreted as nodes and all Hamming distance one neighbors are connected by an edge). The subgraphs of the sequence space that are defined by the sets $f^{-1}(s)$ are called *neutral networks* (Schuster et al., 1994).

The most important global characterization of neutral networks is its average fraction of neutral neighbor $\bar{\lambda}$, usually called the (degree of) neutrality. Neglecting the influence of the distribution of neutral sequences over sequence space, the degree of neutrality will increase with size of the pre-image. Generic properties of neutral networks (Reidys et al., 1997) are readily derived by means of a random graph model. Theory predicts a phase transition like change in the appearance of neutral networks with increasing degree of neutrality at a critical value:

$$\lambda_{\rm cr} \;=\; 1 \;-\; \kappa^{-\frac{1}{\kappa-1}} \;, \tag{1.1}$$

where κ is the size of the genetic alphabet. For example, $\kappa = 4$ for the canonical genetic alphabet $\{\mathsf{A}, \mathsf{U}, \mathsf{G}, \mathsf{C}\}$. If $\bar{\lambda} < \lambda_{\rm cr}$ then the network consists of many isolated parts with one dominating giant component. On the other hand, the network is generically connected if $\bar{\lambda} > \lambda_{\rm cr}$. The critical value $\lambda_{\rm cr}$ is the connectivity threshold. This property of neutral networks reminds of percolation phenomena known from different areas of physics, although the high symmetry of sequence space, with all points being equivalent, introduces a difference in the two concepts.

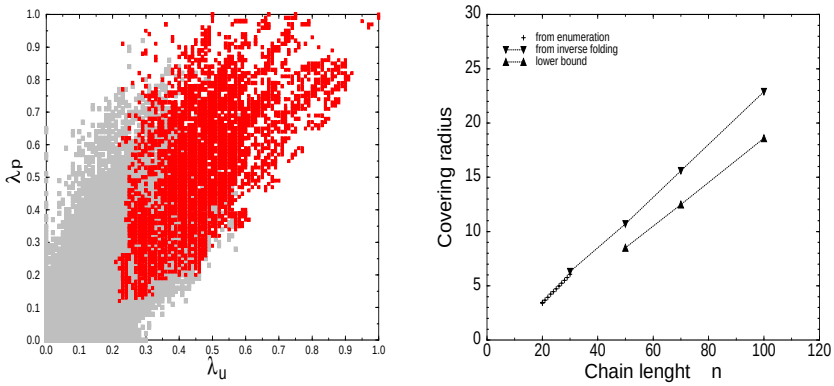
A series of computational studies (Fontana et al., 1993b; Fontana et al., 1993a; Schuster et al., 1994; Huynen et al., 1996b; Grüner et al., 1996a; Grüner et al., 1996b; Fontana and Schuster, 1998a; Fontana and Schuster, 1998b) has in the last decade drawn a rather detailed picture of the genotype-phenotype map of RNA, see also Fig. 1.2.

(i) **More sequences than structures**. For sequence spaces of chain lengths $n \geq 10$ there are orders of magnitude more sequences than structures and hence, the map is many-to-one.

(ii) **Few common and many rare structures**. Relatively few common structures are opposed by a relatively large number of rare structures, some of which are formed by a single sequence only ("relatively" points at the fact that the numbers of both common and rare structures increase exponentially with n, but the exponent for the common structures is smaller than that for the rare ones).

(iii) **Shape space covering**. The distribution of neutral genotypes, these are sequences that fold into the same structure, is approximately random in sequence space. As a result it is possible to define a spherical ball, with a diameter $d_{\rm cov}$ being much smaller than the diameter n of sequence space, which contains on the average for every common structure at least one sequence that folds into it.

(iv) **Existence and connectivity of neutral networks**. Neutral networks, being pre-images of phenotypes or structures in sequence space, of com-



(a) (b)

Figure 1.2. Neutral Networks and Shape Space Covering.
(a) Neutral networks in an exhaustive survey of the GC sequence space with length $n = 30$ (Grüner et al., 1996b) are fragmented (light grey) if the fractions λ_u and λ_p of neutral mutations in the unpaired and paired parts of the sequence are below a threshold value. Above the threshold the the neutral networks consist of one to four connected components. The fragmentation of the single connected component into a small number of (barely) separated subsets can be explained by details of energy based folding model, see (Schuster and Stadler, 1998).
(b) The shape space covering radius $d_{\rm cov}$ scales linearly with the chain length n with a slope $\vartheta \approx 1/4$. Data are taken from (Grüner et al., 1996b).

mon structures are connected unless specific and readily recognizable special features of RNA structures require specific non-random distribution in the $\{\mathsf{A},\mathsf{U},\mathsf{G},\mathsf{C}\}$ sequence space, $\mathcal{Q}^{(\mathsf{AUGC})}$ (For structures formed from sequences over a $\{\mathsf{G},\mathsf{C}\}$ alphabet the connectivity threshold is higher, whereas, at the same time, the mean number of neutral neighbors is smaller).

Shape space covering, item (iii) above, is a consequence of the high susceptibility of RNA secondary structures towards randomly placed point mutations. Computer simulations (Fontana et al., 1993a; Schuster et al., 1994) showed that a small number of point mutations is very likely to cause large changes in the secondary structures: mutations in 10% of the sequence positions already lead almost surely to unrelated structures if the mutated positions are chosen randomly.

The set of nodes of the neutral network $f^{-1}(s)$ is embedded in a compatible set $C(s)$ which includes all sequences that can form the structure s as suboptimal *or* minimum free energy conformation $f^{-1}(S) \subseteq C(s)$. Sequences at the intersection $C(s')\cap C(s'')$ of the compatible sets of two neutral networks in the same sequence space are of actual interest because these sequences can simultaneously carry properties of the different RNA folds. For example, they can

exhibit catalytic activities of two different ribozymes at the same time (Schultes and Bartel, 2000). The intersection theorem (Reidys et al., 1997) states that for all pairs of structures s' and s'' the intersection $C(s') \cap C(s'')$ is always non-empty. In other words, for each arbitrarily chosen pair of structures there will be at least one sequence that can form both. If s' and s'' are both common structures, bistable molecules that have equal preference for both structures are easy to design (Flamm et al., 2000; Höbartner and Micura, 2003). A particularly interesting experimental case is described in (Schultes and Bartel, 2000).

At least, the features (i), (ii), and (iv) of the neutral networks of RNA seem to hold for the more complicated protein spaces as well (Babajide et al., 1997; Babajide et al., 2001), see e.g. (Keefe and Szostak, 2001) for experimental data.

The impact of these features on evolutionary dynamics is discussed in detail in (Huynen et al., 1996b; Schuster, 1995): A population explores sequence space in a diffusion-like manner along the neutral network of a viable structure. Along the fringes of the population novel structures are produced by mutation at a constant rate (Huynen, 1996). Fast diffusion together with perpetual innovation makes these landscapes ideal for evolutionary adaptation (Fontana and Schuster, 1998b) and sets the stage for the evolutionary biotechnology of RNA (Schuster, 1995).

4. Conserved RNA Structures

As we have seen, even a small number of randomly placed point mutations very likely leads to a complete disruption of the RNA structure. Secondary structure elements that are consistently present in a group of sequences with less than, say, 95% average pairwise identity are therefore almost certainly the result of stabilizing selection, not a consequence of the high degree of sequence conservation. If selection acts to preserve structure, then this structure must have some function. It is of considerable practical interest therefore to efficiently compute the consensus structure of a collection of such RNA molecules.

A promising approach towards this goal is the combination of the the "phylogenetic" information that is contained in the sequence co-variations and the information on the (local) thermodynamic stability of the molecules. Such methods for predicting RNA conserved and consensus secondary structure fall into two broad groups: those starting from a multiple sequence alignment and algorithms that attempt to solve the alignment problem and the folding problem simultaneously. The main disadvantage of the latter class of methods (Sankoff, 1985; Tabaska and Stormo, 1997; Gorodkin et al., 1997a; Gorodkin et al., 1997b) is their high computational cost, which makes them unsuitable for long sequences such as 16S or 23S RNAs. Most of the alignment based methods

start from thermodynamics-based folding and use the analysis of sequence covariations or mutual information for post-processing, see e.g., (Le and Zuker, 1991; Lück et al., 1996; Lück et al., 1999; Juan and Wilson, 1999; Hofacker et al., 2002). The converse approach is taken in (Han and Kim, 1993), where ambiguities in the phylogenetic analysis are resolved based on thermodynamic considerations.

It is important to clearly distinguish the consensus structure of a set of RNA sequences from the collection of structural features that are conserved among these sequences. Whenever there are reasons to assume that the structure of the whole molecule is conserved one may attempt to compute a consensus structure. On the other hand, consensus structures are unsuitable when a significant part of the molecule has no conserved structures. RNA virus genomes, for instance contain only local structural patterns (such as the IRES in Picorna viruses or the TAR hairpin in HIV). Such features can be identified with a related approach that is implemented in the algorithm `alidot` algorithm (Hofacker et al., 1998; Hofacker and Stadler, 1999). This program ranks base pairs using both the thermodynamic information contained in the base pairing probability matrix and the information on compensatory, consistent, and inconsistent mutations contained in the multiple sequence alignment. The approach is different from other efforts because it does not assume that the sequences have a single common structure. In this sense `alidot` combines structure prediction and motif search (Dandekar and Hentze, 1995). An implementation of this algorithm is available from `http://www.tbi.univie.ac.at/`. This approach to surveying functional structures goes beyond search software such as `RNAmot` (Gautheret et al., 1990) in that it does not require any *a priori* knowledge of the functional structure motifs and it goes beyond searches for regions that are thermodynamically especially stable or well-defined (Jacobson and Zuker, 1993) in that it returns a specific prediction for a structure if *and only if* there is sufficient evidence for structural conservation.

Of course, it is not possible to determine the function of a conserved structure or structural element without additional experimental input. Nevertheless, knowledge about their location can be used to guide, for instance, deletion studies (Mandl et al., 1998). Knowledge of both protein coding regions and functional RNA structures in the viral genome is needed e.g. to rationally design attenuated mutants for vaccine development.

Structure predictions of a set of sequences are conveniently summarized in the form of Hogeweg-style mountain plots (Hogeweg and Hesper, 1984), Fig. 1.3.

The computation of consensus and conserved RNA structures has been used to compile an *Atlas* of potentially functional RNA motifs in RNA virus genomes. Detailed data are available at present for Picornaviridae (Witwer et al., 2001),

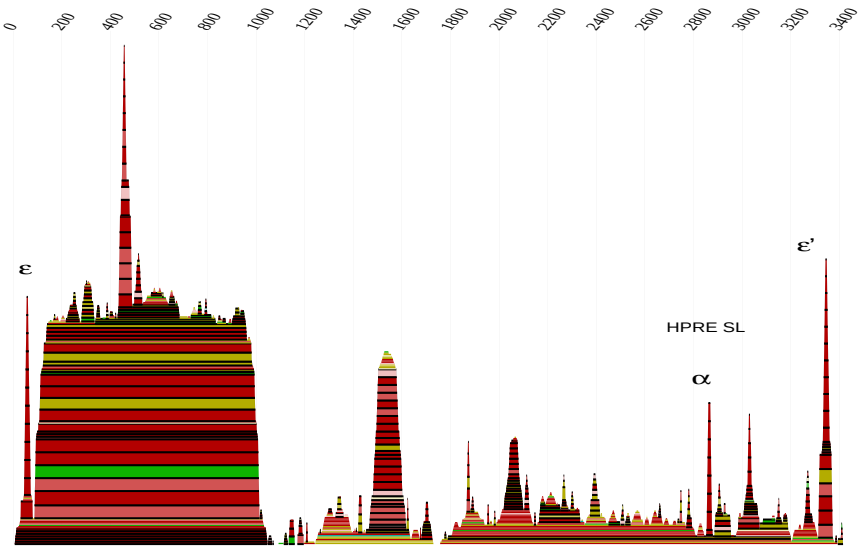


Figure 1.3. Predicted functional RNA structures in the genome of Hepatitis B Virus. The function of the ε, ε', and the α element of the HPRE region, have been determined experimentally. The prediction suggests several new conserved structures with unknown function.
In the "mountain representation" each base pair (i, j) is represented by a bar from i to j. The thickness of the bar indicates its probability or the reliability of the prediction. A color scheme can be used used to indicating sequence covariations. Hue encodes the number of compensatory and consistent mutations, while reduced saturation indicates that a small number of sequences is inconsistent with the structure.

Hepatitis B virus (Stocsits et al., 1999; Kidd-Ljunggren et al., 2000), and Flaviviridae (Thurner et al., 2003).

5. Discussion

Structural genomics, the systematic determination of all macro-molecular structures represented in a genome, is at present focused almost exclusively on proteins. Over the past two decades it has become clear, however, that a variety of RNA molecules have important, and sometimes essential, biological functions beyond their roles as rRNAs, tRNAs, or mRNAs. Given a handful of related RNA sequences, reliable methods now exist to predict conserved functional RNA structures within these RNAs. Because of their small size and fast evolution the genomes of RNA viruses supply fertile ground for such approaches, and databases of functional viral RNA structures are being built up. These functional RNA motifs in the viral genome are just as essential as the encoded proteins, and thus just as promising targets for the development of drugs and vaccines (Mandl et al., 1998; Ying et al., 1999).

The importance of regulatory functions mediated by RNA has only now found more attention through recent studies on the phenomenon of RNA interference (Cogoni and Macino, 2000; Guru, 2000; Hammond et al., 2001). A recent study (Wang et al., 2002) showed, furthermore, that non-coding RNA motives may act as potent "danger motifs" that trigger an adaptive immune system via innate immune receptors. RNA structure thus receives increased attention in molecular medicine.

A comprehensive understanding of the the biology of a cell will ultimately require the knowledge of all encoded RNAs, the molecules with which they interact, and the molecular structures of these complexes (Doudna, 2000). Various approaches to surveying genomic sequences for putative RNA genes have been devised in last few years.

Structure based searches use the known secondary structure of the major classes of functional RNAs. Programs such as `RNAmot` (Gautheret et al., 1990), `tRNAscan` (Lowe and Eddy, 1997), `HyPa` (Gräf et al., 2001), `RNAMotif` (Macke et al., 2001), `bruce` (Laslett et al., 2002), and many others exploit this avenue. An interesting variant that makes use of evolutionary computation is described by (Fogel et al., 2002). Nevertheless, all these approaches are restricted to searching for new members of the few well-established families. The web-based resource `RNAGENiE` uses a neural network that has been trained on a wide variety of functional RNAs (Carter et al., 2001). It is capable of detecting a wider variety of functional RNAs.

Some noncoding RNAs can be found by searching for likely transcripts that do not contain an open reading frame. A survey of the *Escherichia coli* genome for DNA regions that contain a $\sigma 70$ promotor within a short distance of a *Rho*-independent terminator, for instance, resulted in 144 novel possible ncRNAs (Chen et al., 2002). This approach is limited, however, to functional RNAs that are transcribed in the "usual" manner.

Comparative approaches such as the program `QRNA` (Rivas and Eddy, 2001) can detect novel structural RNA genes in a pair of aligned homologous sequences by deciding whether the substitution pattern fits better with (a) synonymous substitutions, which are expected in protein-coding regions, (b) the compensatory mutations consistent with some base-paired secondary structure, or (c) uncorrelated mutations.

Another approach tries to determine functional RNAs by means of structure prediction. The basic assumption is that functional and hence conserved structures will be thermodynamically more stable (Le et al., 1988; Huynen et al., 1996a). While such procedures are capable of detecting some particularly stable features, a recent study (Rivas and Eddy, 2000) concludes that "although a distinct, stable secondary structure is undoubtedly important in most noncoding RNAs, the stability of most noncoding RNA secondary structures is not sufficiently different from the predicted stability of a random sequence to be

useful as a general genefinding approach." Nevertheless, in some special cases such as hyperthermophilic organisms, GC-content (and hence thermodynamic stability) proved sufficient (Klein et al., 2002).

Since most classes of functional RNAs are relatively well conserved while their sequences show little similarities, both comparative procedures and search in single sequences have to rely on structural information. While the prediction of RNA tertiary structures faces much the same problems as protein structure prediction, efficient algorithms exist for handling RNA secondary structure. As we have seen, these methods provide powerful tools for computational studies of RNA structure.
